Efficient computation

“The problem of distinguishing prime numbers from composite and of resolving the latter into their prime factors is ... one of the most important and useful in arithmetic ... Nevertheless we must confess that all methods ... are either restricted to very special cases or are so laborious ... they try the patience of even the practiced calculator ... and do not apply at all to larger numbers.”, Carl Friedrich Gauss, 1798

“For practical purposes, the difference between algebraic and exponential order is often more crucial than the difference between finite and non-finite.”, Jack Edmunds, “Paths, Trees, and Flowers”, 1963

“What is the most efficient way to sort a million 32-bit integers?”, Eric Schmidt to Barack Obama, 2008

“I think the bubble sort would be the wrong way to go.”, Barack Obama.

So far we have been concerned with which functions are computable and which ones are not. In this chapter we look at the finer question of the time that it takes to compute functions, as a function of their input length. This is extremely important in the practice of computing. In introductory courses, coding interviews, and actual algorithm design, terms such as “$O(n)$ running time” are often used in an informal way. People don’t have a precise definition of what a linear-time algorithm is, but rather assume that “they’ll know it when they see it”. However, in this book we will make precise definitions, using our mathematical models of computation. This will allow us to ask (and sometimes answer) questions such as:

- “Is there a function that can be computed in $O(n^2)$ time but not in $O(n)$ time?”
“Are there natural problems for which the best algorithm (and not just the best known) requires $2^{\Omega(n)}$ time?”

In this chapter we will survey some examples of computational problems, for some of which we know efficient (e.g., $n^c$-time for a small constant $c$) algorithms, and for others the best known algorithms are exponential. We want to get a feel as to the kinds of problems that lie on each side of this divide and also see how some seemingly minor changes in formulation can make the (known) complexity of a problem “jump” from polynomial to exponential. We will not formally define the notion of running time in this chapter, and so will use the same “I know it when I see it” notion of an $O(n)$ or $O(n^2)$ time algorithms as the one you’ve seen in introduction to computer science courses. In Chapter 12, we define running time precisely, using Turing Machines and the RAM machines / NAND-RAM formalisms.

While the difference between $O(n)$ and $O(n^2)$ time is often crucial for practice, our focus in this book will be on the difference between polynomial and exponential running time. One of the interesting phenomena of computing is that there is often a kind of a “threshold phenomenon” or “zero-one law” for running time. Many natural problems can either be solved in polynomial running time with a not-too-large exponent (e.g., something like $O(n^2)$ or $O(n^3)$), or require exponential (e.g., at least $2^{\Omega(n)}$ or $2^{\Omega(\sqrt{n})}$) time to solve. The reasons for this phenomenon are still not fully understood, but some light on this is shed by the concept of NP completeness, which we will see in Chapter 14. As we will see, questions about polynomial versus exponential time are often insensitive to the choice of the particular computational model, just as the question of whether a function $F$ is computable is insensitive to whether you use Turing machines, $\lambda$-calculus, or Javascript as your model of computation.

This chapter is merely a tiny sample of the landscape of computational problems and efficient algorithms. If you have not yet seen this material and want to explore it more deeply (which I very much hope you do!), the bibliographical notes contain references to some excellent texts, some of which are available freely on the web.
qualitative question of whether or not a function is computable at all, regardless of the number of operations. Part III of the book, beginning with this chapter, merges the two approaches and contains a quantitative study of computation of infinite functions. In this part we ask how do resources for computing a function scale with the length of the input. In Chapter 12 we define the notion of running time, and the class $P$ of functions that can be computed using a number of steps that scales polynomially with the input length. In Section 12.6 we will relate this class to the models of Boolean circuits and straightline programs that we studied in Part I.

11.1 PROBLEMS ON GRAPHS

In this chapter we discuss several examples of important computational problems. Many of the problems will involve graphs. We have already encountered graphs before (see Section 1.4.4 but let us now quickly recall the basic notation. A graph $G$ consists of a set of vertices $V$ and edges $E$ where each edge is a pair of vertices. In a directed graph, an edge is an ordered pair $(u, v)$, which we sometimes denote as $\overrightarrow{uv}$. In an undirected graph, an edge is an unordered pair (or simply a set) \{u, v\} which we sometimes denote as $\overline{uv}$ or $u \sim v$. An equivalent viewpoint is that an undirected graph is like a directed graph with the property that whenever the edge $\overrightarrow{uv}$ is present then so is the edge $\overleftarrow{uv}$.

In this chapter we will usually assume that the graphs are undirected and simple (i.e., containing no parallel edges or self-loops) unless stated otherwise. We denote by $n$ their number of vertices and $m$ the number of edges. To avoid annoying “edge cases” we will always assume that every vertex touches at least one edge, and so $m \geq n/2$. In fact, we typically think of the vertices as simply the set $[n]$ of the numbers from 0 till $n - 1$. Graphs can be represented either in the adjacency list or adjacency matrix representations. We can transform between these two representations using $O(n^2)$ operations, and hence for our purposes we will mostly consider them as equivalent.

There is a reason that graphs are so ubiquitous in computer science and other sciences. Graphs can be used to model a great many of the data that we encounter. These are not just the “obvious” data such as the road network (which can be thought of as a graph of whose vertices are locations with edges corresponding to road segments), or the web (which can be thought of as a graph whose vertices are web pages with edges corresponding to links), or social networks (which can be thought of as a graph whose vertices are people and the edges correspond to friend relation). Graphs can also denote correlations in data (e.g., graph of observations of features with edges corresponding
380 introduction to theoretical computer science

11.1.1 Finding the shortest path in a graph

The shortest path problem is the task of, given a graph $G = (V, E)$ and two vertices $s, t \in V$, to find the length of the shortest path between $s$ and $t$ (if such a path exists). That is, we want to find the smallest number $k$ such that there are vertices $v_0, v_1, \ldots, v_k$ with $v_0 = s, v_k = t$ and for every $i \in \{0, \ldots, k - 1\}$ an edge between $v_i$ and $v_{i+1}$. Formally, we define $\text{MINPATH} : \{0, 1\}^* \rightarrow \{0, 1\}^*$ to be the function that on input a triple $(G, s, t)$ (represented as a string) outputs the number $k$ which is the length of the shortest path in $G$ between $s$ and $t$ or a string representing no path if no such path exists. (In practice people often want to also find the actual path itself and not just its length; it turns out that the algorithms to compute the length of the path often yield the actual path itself as a byproduct, and so everything we say about the task of computing the length also applies to the task of finding the path.)

If each vertex has at least two neighbors then there can be an exponential number of paths from $s$ to $t$, but fortunately we do not have to enumerate them all to find the shortest path. We can find the shortest path using a breadth first search (BFS), enumerating $s$’s neighbors, and then neighbors’ neighbors, etc., in order. If we maintain the neighbors in a list we can perform a BFS in $O(n^2)$ time, while using a queue we can do this in $O(m)$ time.$^1$ Dijkstra’s algorithm is a well-known generalization of BFS to weighted graphs. More formally, the algorithm for computing the function $\text{MINPATH}$ is described in Algorithm 11.2.

---

$^1$ A queue is a data structure for storing a list of elements in “First In First Out (FIFO)” order. Each “pop” operation removes an element from the queue in the order that they were “pushed” into it; see the Wikipedia page.
Algorithm 11.2 — Shortest path via BFS.

Input: Graph $G = (V, E)$ and vertices $s, t \in V$. Assume $V = [n]$.

Output: Length $k$ of shortest path from $s$ to $t$ or $\infty$ if no such path exists.

1: Let $D$ be length-$n$ array.
2: Set $D[s] = 0$ and $D[i] = \infty$ for all $i \in [n] \setminus \{s\}$.
3: Initialize queue $Q$ to contain $s$.
4: while $S$ non empty do
5: Pop $v$ from $Q$
6: if $v = t$ then
7: return $D[v]$
8: end if
9: for $u$ neighbor of $v$ with $D[u] = \infty$ do
10: Set $D[u] \leftarrow D[v] + 1$
11: Add $u$ to $Q$.
12: end for
13: end while
14: return $\infty$

Since we only add to the queue vertices $w$ with $D[w] = \infty$ (and then immediately set $D[w]$ to an actual number), we never push to the queue a vertex more than once, and hence the algorithm makes $n$ “push” and “pop” operations. For each vertex $v$, the number of times we run the inner loop is equal to the degree of $v$ and hence the total running time is proportional to the sum $2m$ of all degrees. Algorithm 11.2 returns the correct answer since the vertices are added to the queue in the order of their distance from $s$, and hence we will reach $t$ after we have explored all the vertices that are closer to $s$ than $t$.

Remark 11.3 — On data structures. If you’ve ever taken an algorithms course, you have probably encountered many data structures such as lists, arrays, queues, stacks, heaps, search trees, hash tables and many mores. Data structures are extremely important in computer science, and each one of those offers different tradeoffs between overhead in storage, operations supported, cost in time for each operation, and more. For example, if we store $n$ items in a list, we will need a linear (i.e., $O(n)$ time) scan to retrieve one of them, while we achieve the same operation in $O(1)$ time if we used a hash table. However, when we only care about polynomial-time algorithms, such factors of $O(n)$ in the running time will not make much differ-
ence. Similarly, if we don’t care about the difference between $O(n)$ and $O(n^2)$, then it doesn’t matter if we represent graphs as adjacency lists or adjacency matrices. Hence we will often describe our algorithms at a very high level, without specifying the particular data structures that are used to implement them. It should however be always clear that there exists some data structure that will be sufficient for our purposes.

11.1.2 Finding the longest path in a graph
The longest path problem is the task of, given a graph $G = (V, E)$ and two vertices $s, t \in V$, to find the length of the longest simple (i.e., non-intersecting) path between $s$ and $t$. If the graph is a road network, then the longest path might seem less motivated than the shortest path (unless you are the kind of person that always prefers the “scenic route”). But of graphs can and are used to model a variety of phenomena, and in many such cases finding the longest path (and some of its variants) can be very useful. In particular, finding the longest path is a generalization of the famous Hamiltonian path problem which asks for a maximally long simple path (i.e., path that visits all $n$ vertices once) between $s$ and $t$, as well as the notorious traveling salesman problem (TSP) of finding (in a weighted graph) a path visiting all vertices of cost at most $w$. TSP is a classical optimization problem, with applications ranging from planning and logistics to DNA sequencing and astronomy.

Surprisingly, while we can find the shortest path in $O(m)$ time, there is no known algorithm for the longest path problem that significantly improves on the trivial “exhaustive search” or “brute force” algorithm that enumerates all the exponentially many possibilities. Specifically the number of possible paths in an $n$ vertex graph is $\Omega(n^n)$. The best known algorithms for the longest path problem improve on this, but not by much: it takes $\Omega(c^n)$ time for some constant $c > 1$. (At the moment the best record is $c \sim 1.65$ or so; even obtaining an $O(2^n)$ time bound is not that simple, see Exercise 11.1.)

11.1.3 Finding the minimum cut in a graph
Given a graph $G = (V, E)$, a cut is a subset $S$ of $V$ such that $S$ is neither empty nor is it all of $V$. The edges cut by $S$ are those edges where one of their endpoints is in $S$ and the other is in $\overline{S} = V \setminus S$. We denote this set of edges by $E(S, \overline{S})$. If $s, t \in V$ then an $s, t$ cut is a cut such that $s \in S$ and $t \in \overline{S}$ (see Fig. 11.3). The minimum $s, t$ cut problem is the task of finding, given $s$ and $t$, the minimum number $k$ such that there is an $s, t$ cut cutting $k$ edges (the problem is also sometimes phrased as finding the set that achieves this minimum; it turns out that algorithms to compute the number often yield the set as well).

Figure 11.2: A knight’s tour can be thought of as a maximally long path on the graph corresponding to a chessboard where we put an edge between any two squares that can be reached by one step via a legal knight move.
Formally, we define $MINCUT : \{0, 1\}^* \to \{0, 1\}^*$ to be the function that on input a string representing a triple $(G = (V, E), s, t)$ of a graph and two vertices, outputs the minimum number $k$ such that there exists a set $S \subseteq V$ with $s \in S$, $t \notin S$ and $|E(S, \overline{S})| = k$.

The minimum $s, t$ cut problem appears in many applications since minimum cuts often correspond to bottlenecks. For example, in a communication or railroad network the minimum cut between $s$ and $t$ corresponds to the smallest number of edges that, if dropped, will disconnect $s$ from $t$. (This was actually the original motivation for this problem; see Section 11.6.) Similar applications arise in scheduling and planning. In the setting of image segmentation, one can define a graph whose vertices are pixels and whose edges correspond to neighboring pixels of distinct colors. If we want to separate the foreground from the background then we can pick (or guess) a foreground pixel $s$ and background pixel $t$ and ask for a minimum cut between them.

The naive algorithm for computing $MINCUT$ will check all $2^n$ possible subsets of an $n$-vertex graph, but it turns out we can do much better than that. As we’ve seen in this book time and again, there is more than one algorithm to compute the same function, and some of those algorithms might be more efficient than others. Luckily this is one of those cases. There are faster algorithms that compute $MINCUT$ in time which is polynomial in the number of vertices (denoted by $poly(n)$).

**Min-Cut Max-Flow.** We can obtain a polynomial-time algorithm for computing $MINCUT$ using the Max-Flow Min-Cut Theorem. This theory says that the minimum cut between $s$ and $t$ equals the maximum amount of flow we can send from $s$ to $t$, if every edge has unit capacity. Specifically, imagine that every edge of the graph corresponded to a pipe that could carry one unit of fluid per one unit of time (say 1 liter of water per second). Now suppose we want to send a maximum amount of water per second from our source $s$ to the sink $t$. If there is an $s, t$-cut of at most $k$ edges, then this maximum will be at most $k$. Indeed, such a cut $S$ will be a “bottleneck” since at most $k$ units can flow from $S$ to its complement $\overline{S}$. The above reasoning can be used to show that the maximum flow from $s$ to $t$ is at most the value of the minimum $s, t$-cut. The surprising and non-trivial content of the Max-Flow Min-Cut Theorem is that the maximum flow is also at least the value of the minimum cut, and hence computing the cut is the same as computing the flow.

11.1.4 Linear programming
The Max-Flow Min-Cut Theorem reduces the task of computing a minimum cut to the task of computing a maximum flow. However, this still does not show how to compute such a flow. The Ford-Fulkerson
Algorithm is a direct way to compute a flow using incremental improvements. But computing flows in polynomial time is also a special case of a much more general tool known as linear programming.

A flow on a graph \( G \) of \( m \) edges can be modeled as a vector \( x \in \mathbb{R}^m \) where for every edge \( e \), \( x_e \) corresponds to the amount of water per time-unit that flows on \( e \). We think of an edge \( e \) as an ordered pair \((u, v)\) (we can choose the order arbitrarily) and let \( x_e \) be the amount of flow that goes from \( u \) to \( v \). (If the flow is in the other direction then we make \( x_e \) negative.) Since every edge has capacity one, we know that \(-1 \leq x_e \leq 1\) for every edge \( e \). A valid flow has the property that the amount of water leaving the source \( s \) is the same as the amount entering the sink \( t \), and that for every other vertex \( v \), the amount of water entering and leaving \( v \) is the same.

Mathematically, we can write these conditions as follows:

\[
\sum_{e \ni s} x_e + \sum_{e \ni t} x_e = 0
\]

\[
\sum_{e \ni v} x_e = 0 \quad \forall v \in V \setminus \{s,t\}
\]

\[
-1 \leq x_e \leq 1 \quad \forall e \in E
\]

(11.1)

where for every vertex \( v \), summing over \( e \ni v \) means summing over all the edges that touch \( v \).

The maximum flow problem can be thought of as the task of maximizing \( \sum_{e \ni s} x_e \) over all the vectors \( x \in \mathbb{R}^m \) that satisfy the above conditions (11.1). Maximizing a linear function \( \ell(x) \) over the set of \( x \in \mathbb{R}^m \) that satisfy certain linear equalities and inequalities is known as linear programming. Luckily, there are polynomial-time algorithms for solving linear programming, and hence we can solve the maximum flow (and so, equivalently, minimum cut) problem in polynomial time. In fact, there are much better algorithms for maximum flow/minimum-cut, even for weighted directed graphs, with currently the record standing at \( O(\min\{m^{10/7}, m^{1/2}\}) \) time.

Global minimum cut. We can also define the problem of finding the global minimum cut (i.e., the non-empty and non-everything set \( S \) that minimizes the number of edges cut). A polynomial time algorithm for the minimum \( s, t \) cut can be used to solve the global minimum cut in polynomial time by enumerating over all pairs \( s, t \).

11.1.5 Finding the maximum cut in a graph

The maximum cut problem is the task of finding, given an input graph \( G = (V, E) \), the subset \( S \subseteq V \) that maximizes the number of edges cut by \( S \). (We could also define an \( s, t \)-cut variant of the maximum cut like we did for minimum cut; the two variants have similar complexity but we use define maximum cut here in the way that is more common
in the literature.) Like its cousin the minimum cut problem, the maximum cut problem is also very well motivated. For example, it arises in VLSI design, and also has some surprising relation to analyzing the Ising model in statistical physics.

Surprisingly, while there is a polynomial-time algorithm for the minimum cut problem, there is no known algorithm solving maximum cut much faster than the trivial “brute force” algorithm that tries all $2^n$ possibilities for the set $S$.

### 11.1.6 A note on convexity

There is an underlying reason for the sometimes radical difference between the difficulty of maximizing and minimizing a function over a domain. If $D \subseteq \mathbb{R}^n$, then a function $f : D \rightarrow \mathbb{R}$ is convex if for every $x, y \in D$ and $p \in [0, 1]$ $f(px + (1 - p)y) \leq pf(x) + (1 - p)f(y)$. That is, $f$ applied to the $p$-weighted midpoint between $x$ and $y$ is smaller than the $p$-weighted average value of $f$. If $D$ itself is convex (which means that if $x, y$ are in $D$ then so is the line segment between them), then this means that if $x$ is a local minimum of $f$ then it is also a global minimum. The reason is that if $f(y) < f(x)$ then every point $z = px + (1 - p)y$ on the line segment between $x$ and $y$ will satisfy $f(z) \leq pf(x) + (1 - p)f(y) < f(x)$ and hence in particular $x$ cannot be a local minimum. Intuitively, local minima of functions are much easier to find than global ones: after all, any “local search” algorithm that keeps finding a nearby point on which the value is lower, will eventually arrive at a local minima. One example of such a local search algorithm is gradient descent which takes a sequence of small steps, each one in the direction that would reduce the value by the most amount based on the current derivative.

Indeed, under certain technical conditions, we can often efficiently find the minimum of convex functions over a convex domain, and this underlies the reason problems such as minimum cut and shortest path are easy to solve. On the other hand, maximizing a convex function over a convex domain (or equivalently, minimizing a concave function) can often be a hard computational task. A linear function is both convex and concave, which is the reason both the maximization and minimization problems for linear functions can be done efficiently.

The minimum cut problem is not a priori a convex minimization task, because the set of potential cuts is discrete and not continuous. However, it turns out that we can embed it in a continuous and convex set via the (linear) maximum flow problem. The “max flow min cut” theorem ensuring that this embedding is “tight” in the sense that the minimum “fractional cut” that we obtain through the maximum-flow linear program will be the same as the true minimum cut. Un-
fortunately, we don’t know of such a tight embedding in the setting of the maximum cut problem.

The issue of convexity arises time and again in the context of computation. For example, one of the basic tasks in machine learning is empirical risk minimization. This is the task of finding a classifier for a set training examples. That is, the input is a list of labeled examples 

\((x_{m-1}, y_{m-1}), \ldots, (x_{m-1}, y_{m-1})\), where each \(x_i \in \{0, 1\}^n\) and \(y_i \in \{0, 1\}\), and the goal is to find a classifier \(h : \{0, 1\}^n \to \{0, 1\}\) (or sometimes \(h : \{0, 1\}^n \to \mathbb{R}\)) that minimizes the number of errors. More generally, we want to find \(h\) that minimizes

\[ \sum_{i=0}^{m-1} L(y_i, h(x_i)) \]  

(11.2)

where \(L\) is some loss function. When \(L\) is the square loss function 

\[ L(y, y') = (y - y')^2 \]

and \(h\) is a linear function, this corresponds to the well-known convex minimization task of linear regression. In other cases, when the task is non convex, there can be many global or local minima. That said, even if we don’t find the global (or even a local) minima, this continuous embedding can still help us. In particular, when running a local improvement algorithm such as Gradient Descent, we might still find a function \(h\) that is “useful” in the sense of having a small error on future examples from the same distribution.

11.2 BEYOND GRAPHS

Not all computational problems arise from graphs. We now list some other examples of computational problems that are of great interest.

11.2.1 SAT

A propositional formula \(\varphi\) involves \(n\) variables \(x_1, \ldots, x_n\) and the logical operators AND (\(\land\)), OR (\(\lor\)), and NOT (\(\neg\), also denoted as \(\cdot\)). We say that such a formula is in conjunctive normal form (CNF for short) if it is an AND of ORs of variables or their negations (we call a term of the form \(x_i\) or \(\overline{x}_i\) a literal). For example, this is a CNF formula

\[ (x_7 \lor x_{22} \lor x_{15}) \land (x_{37} \lor x_{22}) \land (x_{55} \lor \overline{x}_7) \]  

(11.3)

The satisfiability problem is the task of determining, given a CNF formula \(\varphi\), whether or not there exists a satisfying assignment for \(\varphi\). A satisfying assignment for \(\varphi\) is a string \(x \in \{0, 1\}^n\) such that if \(\varphi\) evaluates to True if we assign its variables the values of \(x\). The SAT problem might seem as an abstract question of interest only in logic but in fact SAT is of huge interest in industrial optimization, with applications including manufacturing planning, circuit synthesis, software verification, air-traffic control, scheduling sports tournaments, and more.
**2SAT.** We say that a formula is a $k$-CNF it is an AND of ORs where each OR involves exactly $k$ literals. The $k$-SAT problem is the restriction of the satisfiability problem for the case that the input formula is a $k$-CNF. In particular, the 2SAT problem is to find out, given a 2-CNФ formula $\varphi$, whether there is an assignment $x \in \{0, 1\}^n$ that satisfies $\varphi$, in the sense that it makes it evaluate to 1 or “True”. The trivial, brute-force, algorithm for 2SAT will enumerate all the $2^n$ assignments $x \in \{0, 1\}^n$ but fortunately we can do much better. The key is that we can think of every constraint of the form $\ell_i \vee \ell_j$ (where $\ell_i, \ell_j$ are literals, corresponding to variables or their negations) as an implication $\ell_i \Rightarrow \ell_j$, since it corresponds to the constraints that if the literal $\ell'_i = \ell_i$ is true then it must be the case that $\ell_j$ is true as well. Hence we can think of $\varphi$ as a directed graph between the $2n$ literals, with an edge from $\ell_i$ to $\ell_j$ corresponding to an implication from the former to the latter. It can be shown that $\varphi$ is unsatisfiable if and only if there is a variable $x_i$ such that there is a directed path from $x_i$ to $\overline{x_i}$ as well as a directed path from $\overline{x_i}$ to $x_i$ (see Exercise 11.2). This reduces 2SAT to the (efficiently solvable) problem of determining connectivity in directed graphs.

**3SAT.** The 3SAT problem is the task of determining satisfiability for 3CNFs. One might think that changing from two to three would not make that much of a difference for complexity. One would be wrong. Despite much effort, we do not know of a significantly better than brute force algorithm for 3SAT (the best known algorithms take roughly $1.3^n$ steps).

Interestingly, a similar issue arises time and again in computation, where the difference between two and three often corresponds to the difference between tractable and intractable. We do not fully understand the reasons for this phenomenon, though the notions of NP completeness we will see later does offer a partial explanation. It may be related to the fact that optimizing a polynomial often amounts to equations on its derivative. The derivative of a a quadratic polynomial is linear, while the derivative of a cubic is quadratic, and, as we will see, the difference between solving linear and quadratic equations can be quite profound.
11.2.2 Solving linear equations

One of the most useful problems that people have been solving time and again is solving \( n \) linear equations in \( n \) variables. That is, solve equations of the form

\[
\begin{align*}
    a_{0,0}x_0 + a_{0,1}x_1 &+ \cdots + a_{0,n-1}x_{n-1} = b_0 \\
    a_{1,0}x_0 + a_{1,1}x_1 &+ \cdots + a_{1,n-1}x_{n-1} = b_1 \\
    \vdots &+ \vdots + \vdots = \vdots \\
    a_{n-1,0}x_0 + a_{n-1,1}x_1 &+ \cdots + a_{n-1,n-1}x_{n-1} = b_{n-1}
\end{align*}
\]

(11.4)

where \( \{a_{i,j}\}_{i,j \in [n]} \) and \( \{b_i\}_{i \in [n]} \) are real (or rational) numbers. More compactly, we can write this as the equations \( Ax = b \) where \( A \) is an \( n \times n \) matrix, and we think of \( x, b \) are column vectors in \( \mathbb{R}^n \).

The standard Gaussian elimination algorithm can be used to solve such equations in polynomial time (i.e., determine if they have a solution, and if so, to find it). As we discussed above, if we are willing to allow some loss in precision, we even have algorithms that handle linear inequalities, also known as linear programming. In contrast, if we insist on integer solutions, the task of solving for linear equalities or inequalities is known as integer programming, and the best known algorithms are exponential time in the worst case.

**Remark 11.4 — Bit complexity of numbers.** Whenever we discuss problems whose inputs correspond to numbers, the input length corresponds to how many bits are needed to describe the number (or, as is equivalent up to a constant factor, the number of digits in base 10, 16 or any other constant). The difference between the length of the input and the magnitude of the number itself can be of course quite profound. For example, most people would agree that there is a huge difference between having a billion (i.e. \( 10^9 \) dollars and having nine dollars. Similarly there is a huge difference between an algorithm that takes \( n \) steps on an \( n \)-bit number and an algorithm that takes \( 2^n \) steps.

One example, is the problem (discussed below) of finding the prime factors of a given integer \( N \). The natural algorithm is to search for such a factor by trying all numbers from 1 to \( N \), but that would take \( N \) steps which is exponential in the input length, which is number of bits needed to describe \( N \). (The running time of this algorithm can be easily improved to roughly \( \sqrt{N} \), but this is still exponential (i.e., \( 2^{n/2} \) in the number \( n \) of bits to describe \( N \).) It is an important and long open question whether there is such an algorithm that runs in time polynomial in the input length (i.e., polynomial in \( \log N \)).
11.2.3 Solving quadratic equations

Suppose that we want to solve not just linear but also equations involving quadratic terms of the form $a_{i,j,k}x_jx_k$. That is, suppose that we are given a set of quadratic polynomials $p_1, \ldots, p_m$ and consider the equations $\{p_i(x) = 0\}$. To avoid issues with bit representations, we will always assume that the equations contain the constraints $\{x_i^2 - x_i = 0\}_{i \in [n]}$. Since only 0 and 1 satisfy the equation $a^2 - a$, this assumption means that we can restrict attention to solutions in $\{0, 1\}^n$.

Solving quadratic equations in several variables is a classical and extremely well motivated problem. This is the generalization of the classical case of single-variable quadratic equations that generations of high school students grapple with. It also generalizes the quadratic assignment problem, introduced in the 1950’s as a way to optimize assignment of economic activities. Once again, we do not know a much better algorithm for this problem than the one that enumerates over all the $2^n$ possibilities.

11.3 MORE ADVANCED EXAMPLES

We now list a few more examples of interesting problems that are a little more advanced but are of significant interest in areas such as physics, economics, number theory, and cryptography.

11.3.1 Determinant of a matrix

The determinant of a $n \times n$ matrix $A$, denoted by $\det(A)$, is an extremely important quantity in linear algebra. For example, it is known that $\det(A) \neq 0$ if and only if $A$ is nonsingular, which means that it has an inverse $A^{-1}$, and hence we can always uniquely solve equations of the form $Ax = b$ where $x$ and $b$ are $n$-dimensional vectors. More generally, the determinant can be thought of as a quantitative measure as to what extent $A$ is far from being singular. If the rows of $A$ are “almost” linearly dependent (for example, if the third row is very close to being a linear combination of the first two rows) then the determinant will be small, while if they are far from it (for example, if they are orthogonal to one another, then the determinant will be large). In particular, for every matrix $A$, the absolute value of the determinant of $A$ is at most the product of the norms (i.e., square root of sum of squares of entries) of the rows, with equality if and only if the rows are orthogonal to one another.

The determinant can be defined in several ways. One way to define the determinant of an $n \times n$ matrix $A$ is:

$$
\det(A) = \sum_{\pi \in S_n} \text{sign}(\pi) \prod_{i \in [n]} A_{i, \pi(i)}
$$

(11.5)
where $S_n$ is the set of all permutations from $[n]$ to $[n]$ and the sign of a permutation $\pi$ is equal to $-1$ raised to the power of the number of inversions in $\pi$ (pairs $i, j$ such that $i > j$ but $\pi(i) < \pi(j)$).

This definition suggests that computing $\det(A)$ might require summing over $|S_n|$ terms which would take exponential time since $|S_n| = n! > 2^n$. However, there are other ways to compute the determinant. For example, it is known that $\det$ is the only function that satisfies the following conditions:

1. $\det(AB) = \det(A)\det(B)$ for every square matrices $A, B$.

2. For every $n \times n$ triangular matrix $T$ with diagonal entries $d_0, \ldots, d_{n-1}$, $\det(T) = \prod_{i=0}^{n} d_i$. In particular $\det(I) = 1$ where $I$ is the identity matrix. (A triangular matrix is one in which either all entries below the diagonal, or all entries above the diagonal, are zero.)

3. $\det(S) = -1$ where $S$ is a “swap matrix” that corresponds to swapping two rows or two columns of $I$. That is, there are two coordinates $a, b$ such that for every $i, j$, $S_{i,j} = \begin{cases} 1 & i = j, i \notin \{a, b\} \\ 1 & \{i, j\} = \{a, b\} \\ 0 & \text{otherwise} \end{cases}$.

Using these rules and the Gaussian elimination algorithm, it is possible to tell whether $A$ is singular or not, and in the latter case, decompose $A$ as a product of a polynomial number of swap matrices and triangular matrices. (Indeed one can verify that the row operations in Gaussian elimination corresponds to either multiplying by a swap matrix or by a triangular matrix.) Hence we can compute the determinant for an $n \times n$ matrix using a polynomial time of arithmetic operations.

### 11.3.2 Permanent of a matrix

Given an $n \times n$ matrix $A$, the permanent of $A$ is defined as

$$\perm(A) = \sum_{\pi \in S_n} \prod_{i \in [n]} A_{i, \pi(i)}.$$

That is, $\perm(A)$ is defined analogously to the determinant in (11.5) except that we drop the term $\text{sign}(\pi)$. The permanent of a matrix is a natural quantity, and has been studied in several contexts including combinatorics and graph theory. It also arises in physics where it can be used to describe the quantum state of multiple Boson particles (see here and here).
Permanent modulo 2. If the entries of $A$ are integers, then we can define the Boolean function $\text{perm}_2$ which outputs on input a matrix $A$ the result of the permanent of $A$ modulo 2. It turns out that we can compute $\text{perm}_2(A)$ in polynomial time. The key is that modulo 2, $-x$ and $+x$ are the same quantity and hence, since the only difference between (11.5) and (11.6) is that some terms are multiplied by $-1$, $\det(A) \mod 2 = \text{perm}(A) \mod 2$ for every $A$.

Permanent modulo 3. Emboldened by our good fortune above, we might hope to be able to compute the permanent modulo any prime $p$ and perhaps in full generality. Alas, we have no such luck. In a similar “two to three” type of a phenomenon, we do not know of a much better than brute force algorithm to even compute the permanent modulo 3.

11.3.3 Finding a zero-sum equilibrium

A zero sum game is a game between two players where the payoff for one is the same as the penalty for the other. That is, whatever the first player gains, the second player loses. As much as we want to avoid them, zero sum games do arise in life, and the one good thing about them is that at least we can compute the optimal strategy.

A zero sum game can be specified by an $n \times n$ matrix $A$, where if player 1 chooses action $i$ and player 2 chooses action $j$ then player one gets $A_{i,j}$ and player 2 loses the same amount. The famous Min Max Theorem by John von Neumann states that if we allow probabilistic or “mixed” strategies (where a player does not choose a single action but rather a distribution over actions) then it does not matter who plays first and the end result will be the same. Mathematically the min max theorem is that if we let $\Delta_n$ be the set of probability distributions over $[n]$ (i.e., non-negative columns vectors in $\mathbb{R}^n$ whose entries sum to 1) then

$$\max_{p \in \Delta_n} \min_{q \in \Delta_n} p^\top A q = \min_{q \in \Delta_n} \max_{p \in \Delta_n} p^\top A q$$  \hspace{1cm} (11.7)

The min-max theorem turns out to be a corollary of linear programming duality, and indeed the value of (11.7) can be computed efficiently by a linear program.

11.3.4 Finding a Nash equilibrium

Fortunately, not all real-world games are zero sum, and we do have more general games, where the payoff of one player does not necessarily equal the loss of the other. John Nash won the Nobel prize for showing that there is a notion of equilibrium for such games as well. In many economic texts it is taken as an article of faith that when actual agents are involved in such a game then they reach a Nash...
equilibrium. However, unlike zero sum games, we do not know of an efficient algorithm for finding a Nash equilibrium given the description of a general (non zero sum) game. In particular this means that, despite economists’ intuitions, there are games for which natural strategies will take exponential number of steps to converge to an equilibrium.

11.3.5 Primality testing
Another classical computational problem, that has been of interest since the ancient greeks, is to determine whether a given number \( N \) is prime or composite. Clearly we can do so by trying to divide it with all the numbers in \( 2, \ldots, N - 1 \), but this would take at least \( N \) steps which is exponential in its bit complexity \( n = \log N \). We can reduce these \( N \) steps to \( \sqrt{N} \) by observing that if \( N \) is a composite of the form \( N = PQ \) then either \( P \) or \( Q \) is smaller than \( \sqrt{N} \). But this is still quite terrible. If \( N \) is a 1024 bit integer, \( \sqrt{N} \) is about \( 2^{512} \), and so running this algorithm on such an input would take much more than the lifetime of the universe.

Luckily, it turns out we can do radically better. In the 1970’s, Rabin and Miller gave probabilistic algorithms to determine whether a given number \( N \) is prime or composite in time \( \text{poly}(n) \) for \( n = \log N \). We will discuss the probabilistic model of computation later in this course. In 2002, Agrawal, Kayal, and Saxena found a deterministic \( \text{poly}(n) \) time algorithm for this problem. This is surely a development that mathematicians from Archimedes till Gauss would have found exciting.

11.3.6 Integer factoring
Given that we can efficiently determine whether a number \( N \) is prime or composite, we could expect that in the latter case we could also efficiently find the factorization of \( N \). Alas, no such algorithm is known. In a surprising and exciting turn of events, the non existence of such an algorithm has been used as a basis for encryptions, and indeed it underlies much of the security of the world wide web. We will return to the factoring problem later in this course. We remark that we do know much better than brute force algorithms for this problem. While the brute force algorithms would require \( 2^{\Omega(n)} \) time to factor an \( n \)-bit integer, there are known algorithms running in time roughly \( 2^{O(\sqrt{n})} \) and also algorithms that are widely believed (though not fully rigorously analyzed) to run in time roughly \( 2^{O(n^{1/3})} \). (By “roughly” we mean that we neglect factors that are polylogarithmic in \( n \).)
11.4 OUR CURRENT KNOWLEDGE

The difference between an exponential and polynomial time algorithm might seem merely “quantitative” but it is in fact extremely significant. As we’ve already seen, the brute force exponential time algorithm runs out of steam very very fast, and as Edmonds says, in practice there might not be much difference between a problem where the best algorithm is exponential and a problem that is not solvable at all. Thus the efficient algorithms we mention above are widely used and power many computer science applications. Moreover, a polynomial-time algorithm often arises out of significant insight to the problem at hand, whether it is the “max-flow min-cut” result, the solvability of the determinant, or the group theoretic structure that enables primality testing. Such insight can be useful regardless of its computational implications.

At the moment we do not know whether the “hard” problems are truly hard, or whether it is merely because we haven’t yet found the right algorithms for them. However, we will now see that there are problems that do inherently require exponential time. We just don’t know if any of the examples above fall into that category.

Lecture Recap

- There are many natural problems that have polynomial-time algorithms, and other natural problems that we’d love to solve, but for which the best known algorithms are exponential.
- Often a polynomial time algorithm relies on discovering some hidden structure in the problem, or finding a surprising equivalent formulation for it.
- There are many interesting problems where there is an exponential gap between the best known algorithm and the best algorithm that we can rule out. Closing this gap is one of the main open questions of theoretical computer science.

11.5 EXERCISES

Exercise 11.1 — exponential time algorithm for longest path. The naive algorithm for computing the longest path in a given graph could take more than $n!$ steps. Give a $\text{poly}(n)2^n$ time algorithm for the longest path problem in $n$ vertex graphs.\(^2\)

Exercise 11.2 — 2SAT algorithm. For every 2CNF $\varphi$, define the graph $G_\varphi$ on $2n$ vertices corresponding to the literals $x_1, \ldots, x_n, \overline{x_1}, \ldots, \overline{x_n}$, such that there is an edge $\vec{e_i} \vec{e_j}$ iff the constraint $l_i \lor l_j$ is in $\varphi$. Prove that $\varphi$

\(^2\) Hint: Use dynamic programming to compute for every $s, t \in [n]$ and $S \subseteq [n]$ the value $P(s, t, S)$ which equals 1 if there is a simple path from $s$ to $t$ that uses exactly the vertices in $S$. Do this iteratively for $S$’s of growing sizes.
is unsatisfiable if and only if there is some \( i \) such that there is a path from \( x_i \) to \( \overline{x}_i \) and from \( \overline{x}_i \) to \( x_i \) in \( G_\varphi \). Show how to use this to solve 2SAT in polynomial time.

11.6 BIBLIOGRAPHICAL NOTES

The classic undergraduate introduction to algorithms text is [Cor+09]. Two texts that are less “encyclopedic” are Kleinberg and Tardos [KT06], and Dasgupta, Papadimitriou and Vazirani [DPV08]. Jeff Erickson’s book is an excellent algorithms text that is freely available online.

The origins of the minimum cut problem date to the cold war. Specifically, Ford and Fulkerson discovered their max-flow/min-cut algorithm in 1955 as a way to find out the minimum amount of train tracks that would need to be blown up to disconnect Russia from the rest of Europe. See the survey [Sch05] for more.

11.7 FURTHER EXPLORATIONS

Some topics related to this chapter that might be accessible to advanced students include: (to be completed)
